# Strings II

### Review

- Strings are stored character by character.
- Can access each character individually by using an index:

#### New

 Negative indexing can be used. (Particularly useful for getting characters near the end of a string.)

### The basic string for loop

• Use this whenever you need to process a string one character at a time.

# assume s is a string variable
for pos in range(0, len(s)):
 # do something with s[pos]

# s = "banana" total = 0for pos in range(0, len(s)): if s[pos] == "a": total = total + 10 1 2 3 4 5 "n"

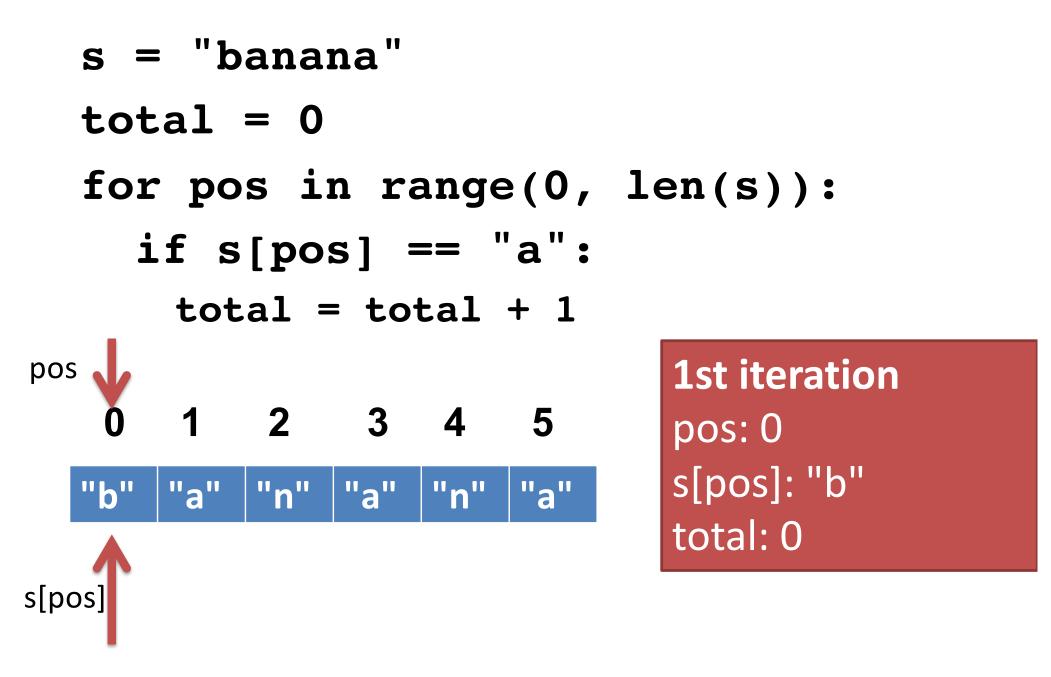

"a"

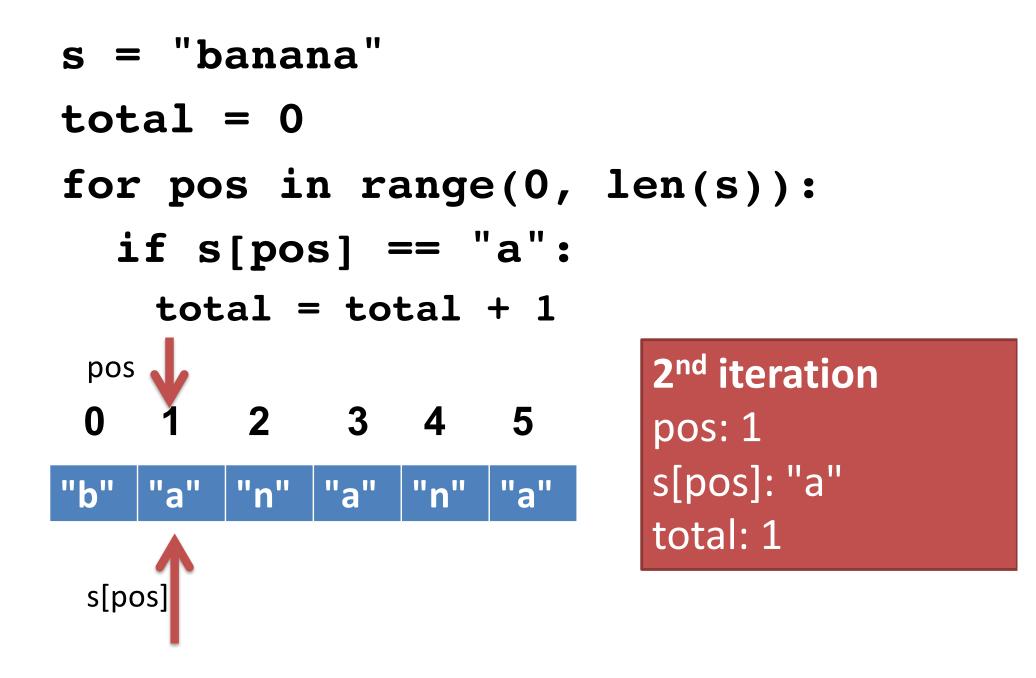

"a"

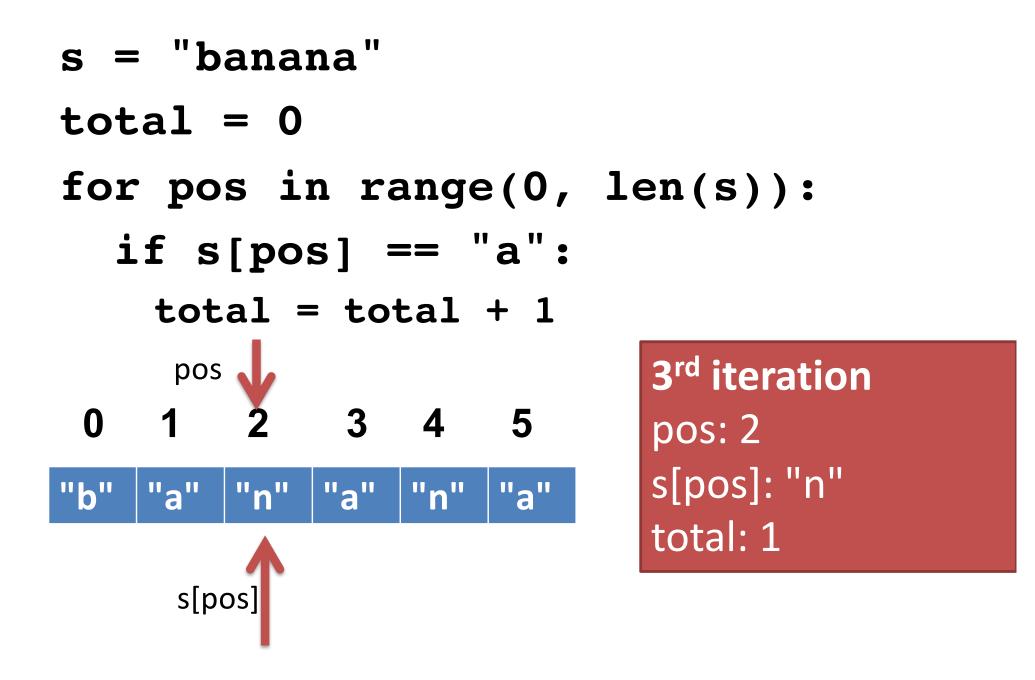

"b"

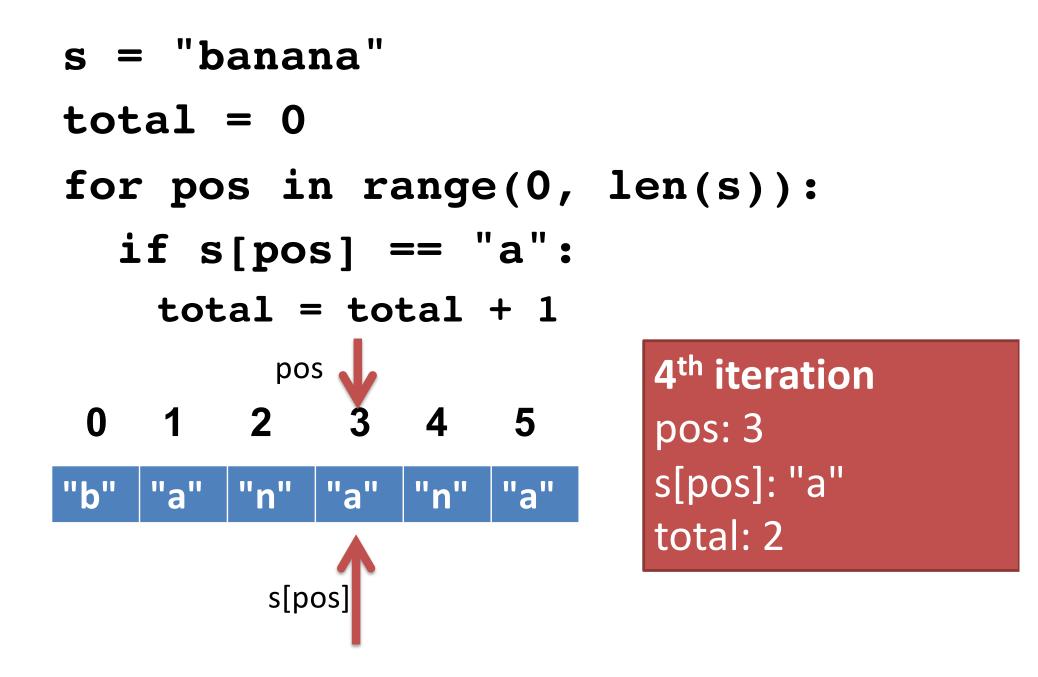

"n"

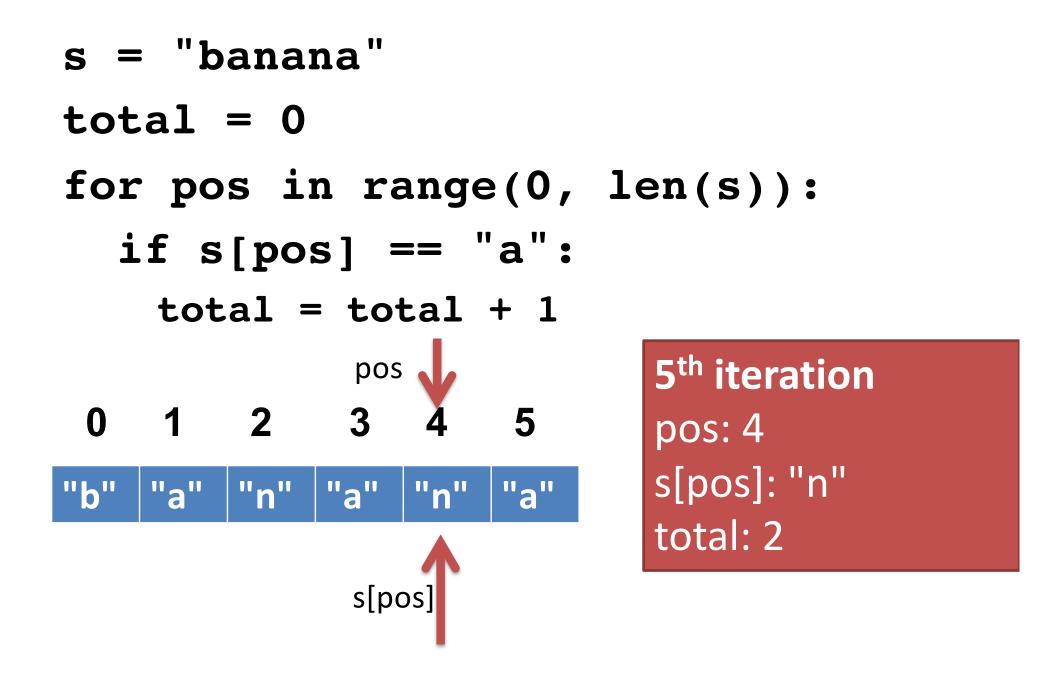

"a"

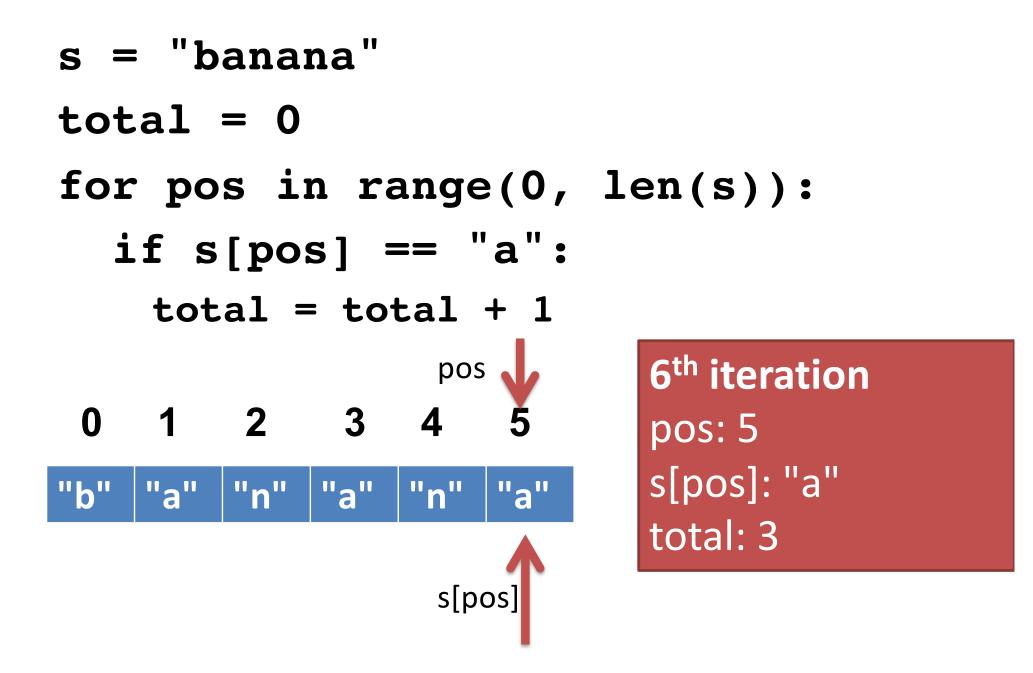

#### Algorithm -> Function

 Counting the number of a certain character in a string seems like a good candidate for a function.

```
def count_a(s):
   total = 0
   for pos in range(0, len(s)):
      if s[pos] == "a"
      total = total + 1
   return total
```

```
def count a(s):
  total = 0
  for pos in range(0, len(s)):
    if s[pos] == "a":
      total = total + 1
  return total
def main():
  name = input("What is your name? ")
  freq = count a(name)
  print("Your name has", freq, "A's in it.")
```

- Step 1: Change the count function so it takes a second argument called letter. The function should count the number of times that letter occurs in the string (instead of only lowercase a's).
- Step 2: Change the main function so that the user can type in their name and a letter and the program prints the frequency of that letter in their name.
- Step 3: Write a function count\_dups that counts (and returns) all occurrences of consecutive duplicated letters in a string.

- e.g., count\_dups("balloon") returns 2.

Not all string problems are solved with for loops.

def get\_initial(firstname):
 first\_init = firstame[0]
 return first\_init

# **String Concatenation**

- Combines two strings into a new, longer string.
- Uses the same plus sign as addition.
- s1 = "CS141"
- s2 = "rocks!"
- bigstring = s1 + s2

print(bigstring)

# prints CS141rocks!

## **String Concatenation**

- Unlike **print()**, string concatenation does not put spaces between your strings.
- s1 = "CS141"
- s2 = "rocks!"
- bigstring = s1 + " " + s2

print(bigstring)

# prints CS141 rocks!

# Sample problem

- All professor email addresses at Rhodes are constructed from the professor's last name, followed by the initial letter of their first name.
- We want to design a function that takes a prof's first and last name and returns their email address.

```
def make prof email(first, last):
  init = first[0]
  address = last + init + "@rhodes.edu"
  return address
def main():
  firstname = input("First name: ")
  lastname = input("Last name: ")
  addr = make_prof email(firstname, lastname)
  print("Email:", addr)
```

# You try it

- Write a function make\_student\_email that creates (and returns) a student email address.
- The function should take four parameters: first name, last name, middle name, and class year.
- Challenge: Modify the function so it takes only two parameters: someone's full name (one string with first, middle, and last names within it) and class year.

- A fundamental problem when using strings is computing a *substring*, or a string *slice*.
- We want to tell Python
  - take some string,
  - give me all the characters starting from one index,
  - and ending at another index.
- Fortunately, this is built into Python!

- Two ways to use square brackets.
- 1 number inside the brackets:
  - returns *exactly one* character of a string.
  - if s = "Computer, then s[0] returns "C"
- 2 numbers inside the brackets:
  - returns a *substring* or string *slice*.

**s[a:b]** gives you a string slice of string **s** starting from index **a** and ending at index **b-1**.

"C" "o" "m" "p" "u" "t" "e" "r"

s[0:1] -> "C" just like s[0]

- s[0:2] -> "Co"
- s[0:7] -> "Compute"
- s[3:6] -> "put"

s[0:8] -> "Computer"

# More fun with indices

- Indices can also be negative.
- A negative index counts from the right side of the string, rather than the left.

```
s = "Computer"
```

| <pre>print(s[-1])</pre>        | # | prints | r      |
|--------------------------------|---|--------|--------|
| <pre>print(s[-3:len(s)])</pre> | # | prints | ter    |
| <pre>print(s[1:-1])</pre>      | # | prints | ompute |

- Slices don't need both left and right indices.
- Missing left index:

– Python assumes you meant 0 [far left of string]

• Missing right index:

Python assumes you meant len(s) [far right of string]

```
s = "Computer"
```

```
print(s[1:])
```

```
print(s[:5])
```

```
print(s[-2:])
```

- # prints omputer
  - # prints Compu
  - # prints er

#### Indices don't have to be literal numbers

Say we have this code:

name = input("type in your name: ")

x = int(len(name) / 2)

print(name[0:x])

What does this print?
